Cognitive Radio Networks have emerged in the last decades as a solution of two problems: spectrum underutilization and spectrum scarcity. In this work we propose a dynamic spectrum sharing mechanism, where primary users have strict priority over secondary ones, in order to improve the mean spectrum utilization with the objective of providing to secondary users a satisfactory grade of service with a small interruption probability. We study a stochastic model for Cognitive Radio Networks with fluid limits techniques. Our main findings consist in a Gaussian limit theorem in the sub-critical case, and a non-Gaussian limit theorem, under a different scaling scheme, in the critical case. These results provide us practical QoS criteria for sharing policies. We support our analysis with representative simulated examples in both scenarios.

CCS Concepts: • Mathematics of computing → Probability and statistics; • Networks → Network
 performance modeling; Network dynamics; Network performance analysis.

Additional Key Words and Phrases: Cognitive radio networks, QoS, fluid limits, asymptotic distribution

Claudina Rattaro, Laura Aspirot, Ernesto Mordecki, and Pablo Belzarena. 2019. QoS provision in a dynamic channel allocation based on admission control decisions. *ACM Trans. Model. Perform. Eval. Comput. Syst.* 1, 1, Article 1 (January 2019), 30 pages. https://doi.org/10.1145/3372786

## 1 INTRODUCTION

During the last two decades we have seen an explosive development of wireless networks which is reflected on the widely extended use of wireless technologies in our everyday lives (e.g. mobile phones, sensors, laptops). Consequently the demand for electromagnetic spectrum has increased to unprecedented levels resulting in the spectrum scarcity problem. In spite of this, spectrum utilization measurements have shown that licensed bands are vastly underutilized while unlicensed bands are too crowded [6, 21, 39]. The significant underutilization occurs even in densely populated urban areas. Therefore, it is vital to move forward with a means for better utilization of the spectrum.

Nowadays industrial and academic communities are focusing much of their efforts to define the main characteristics of the fifth-generation of mobile networks. It is expected that 5G connections will appear on the scene in 2020 and will grow more than a thousand percent from 2.3 million in 2020 to over 25 million in 2021 [11]. With this in mind, how to optimize the spectrum capacity becomes

a key ingredient in 5G system design. In this regard Cognitive Radio represents an attractive
 candidate, especially for 5G networs [1, 17, 19, 28, 34].

The concept of Cognitive Radio (CR) was introduced by Mitola [26, 27]. CR represents a promising 52 technology which, based on dynamic spectrum access, strives at solving the important problems 53 that we mentioned before: spectrum underutilization and spectrum scarcity. In this paradigm we 54 can identify two classes of users: primary and secondary. Primary users (PUs) are those for which 55 a certain portion of the spectrum has been allocated to (often in the form of a paid contract). 56 Secondary users (SUs) are devices which are capable of detecting unused licensed bands and adapt 57 58 their transmission parameters for using them. The key requirement in this context is that the PUs ought to be as little affected as possible by the presence of SUs. One challenge then is to distribute 59 the spectrum holes efficiently and fairly. Another goal is to provide quality of service (QoS) to PUs 60 and also to SUs. 61

62 In what follows we focus on the analysis and characterization of a dynamic spectrum sharing 63 mechanism where PUs have strict priority over secondary ones. We present tools and criteria that can be used in order to improve the mean spectrum utilization with the commitment of providing 64 to SUs a satisfactory grade of service and a small interruption probability. We are interested in SUs 65 whose service cannot be interrupted with high probability (like a phone call or other interactive 66 services). For these services it is preferable to be rejected and to avoid the situation where the 67 connection is established and then interrupted. These decisions (start service or not) represent a 68 mechanism that can be adopted by the SUs as a sort of admission control policy. We analyze two 69 indicators of these types of systems: the mean spectrum utilization and the probability that the 70 system is working at its capacity limit which is related with the interruption probability for SUs 71 services. Associated with this last issue we analyze a possible admission control policy in order to 72 reduce this probability. 73

In more detail we consider a scenario with *C* subchannels to be distributed between SUs and 74 PUs, and where PUs have strict priority. That is to say, we assume a scenario without spatial reuse 75 of subchannels where if a PU arrives when all the resources are in use, one of the SUs will be 76 deallocated immediately. For instance, consider a cellular network that employs frequency division 77 duplexing where the operator has C frequency bands (subchannels) to be assigned to its users 78 79 (PUs). If the primary network is LTE, we can assume a subchannel as one or more resource blocks. Another example is given by the digital TV spectrum bands. In both scenarios, if there are free 80 resources, the SUs could use them with the constraint that their communications can be interrupted 81 at any time. However, there are some differences between both examples: in a cellular network 82 PUs can use any of the *C* subchannels, but in the case of digital TV each TV channel has its own 83 frequency band. Then we assume in our model that when a PU arrives while a SU is using its 84 subchannel, and there are free subchannels, this SU can be moved instantly to another unused 85 band, without any consequence to its service. If there is not a free subchannel (all of them are 86 busy), the SUs communication will be interrupted with consequences to its QoS. As our model 87 takes into account only the number of subchannels that are being used by PUs and SUs, if there are 88 free subchannels, the case of a PU that arrives to its subchannel and a SU must be moved instantly 89 90 to another free one will be modeled as if the PU arrives to a free subchannel.

There are some previous works which contribute in this direction, with the most representative examples being [2, 20, 23, 40]. In [20] the authors study a spectrum sharing allocation for PUs and SUs where preemption can occur. Similar to our model, they consider that a SU call is immediately dropped when all resources are in use and a PU call arrives. However, they only analyze the queuing system (as two M/M/C/C queues) but do not address the possibility of providing certain level of QoS to the users. Therefore they do not investigate the behavior of the system when admission control mechanisms are applied. In [23] the authors study preemptive and non-preemptive priority

QoS provision in a dynamic channel allocation based on admission control decisions

99 queues. The main difference to our model is that the affected SU (which is deallocated when a PU needs a subchannel and are all in use) has to wait in the system until a subchannel is available again 100 (in the paper it is assumed the existence of a buffer). In our case we consider a total interruption of 101 the communication, with no buffer. Our assumption is more reasonable in services like a phone 102 call or other interactive services. On the other hand, in [40] the authors study the stationary 103 regime for a multiclass queue with preemption, similar to ours, obtaining a recursive expression 104 for the probability of interruption. Finally in [2], although the authors study an admission control 105 106 mechanism over SUs, they do no obtain an analytic expression of QoS metrics and only evaluate 107 them through simulations.

In this work we model the cognitive radio network as a two-dimensional continuous time Markov 108 chain (CTMC). In our approach the Markovian structure allows us to analyze its asymptotic behavior 109 by means of a deterministic approximation obtained as a solution of a differential equation, i.e. 110 its fluid limit. Under some regularity hypotheses on transition rates, the fluid limit is the solution 111 112 of an ordinary differential equation (ODE). In cases as ours, with discontinuous transition rates, the fluid limit is a piecewise smooth dynamical system (PWSDS). We characterize the system 113 behavior studying the PWSDS fixed points and we show that, in many cases, a SUs admission 114 control mechanism is required in order to ensure a low probability of service interruption. Some 115 preliminary results were published in our previous article [30]. 116

117 In the present paper we extend the analysis to a probabilistic admission control mechanism and most importantly, we incorporate aspects such as the description of the asymptotic distribution 118 associated with the fluid limit. This distribution depends strongly on the fixed points of the 119 deterministic approximation, both with and without admission control, and we find, depending on 120 the parameters of the model, Gaussian and non-Gaussian asymptotic distributions. The asymptotic 121 distribution permits the analysis of the interruption probability for SUs giving confidence bounds 122 valid when the number of users is large. In the case of non-Gaussian distribution, the stationary 123 regime and its limit are described explicitly in a simplified case. Using our results we also present 124 some practical network design criteria. In particular, the asymptotic distribution that was only 125 mentioned in [30] is developed here. 126

Applications of fluid models to telecommunications appeared in the literature and were widely 127 developed in the last decade. Some recent examples include for instance: peer-to-peer systems 128 and mobile networks (see for example [3, 5, 14, 29, 31, 32, 37] and references therein). In particular 129 concerning applications to CR networks there are some related works that we would like to highlight. 130 In [38] the authors use a fluid model to study SU's queuing delay performance. In [41] they study 131 the coexistence of two wireless networks with different priorities and compare throughput and 132 delay obtained in both networks. On the other hand, [42] is focused on the collaborative sensing 133 within the SUs and its impact in QoS. In these papers the authors analyze the delay and throughput 134 in different CR scenarios, so their results can be complementary to ours where we analyze the 135 interruption probability. 136

The rest of the paper is structured as follows. After this introductory section, in Section 2, we describe our model of spectrum sharing in CR networks. Section 3 presents the fluid model and in the following subsections we show our analysis and characterization of the behavior of the system under different admission control policies. We study the system for three different admission control policies: free, deterministic and probabilistic. For all cases we introduce a fluid limit, and study the system through it , analyzing fixed points and the asymptotic distribution around the limit. Finally, we conclude and discuss future work in Section 4.

### 148 2 MODEL DESCRIPTION

In this section we introduce our stochastic model for the number of primary and secondary users in the system as a two-dimensional CTMC. This is a comprehensive and although simple model for the system under study, however, it does not have an analytical solution. Therefore, we introduce in Section 3 a scaled version of the CTMC, in order to find a fluid limit that allows us to study the system analytically.

We model the arrival processes for both type of users as independent Poisson processes, and the service durations are also independent and exponentially distributed random variables. We also model the possibility of admission control decisions when a SU arrives to the system (SUs shall decide, depending on the state of the system, whether to enter or not). We associate one user with one channel.

In this context a general model and its variations due to the admission control policy assumptions are stated in the following definitions.

Definition 2.1 (General model). Consider a CTMC  $(X_1, X_2)$  defined as follows.

- $X_1(t), X_2(t)$ : number of PUs and SUs at time *t* respectively,
  - *C*: total number of identical subchannels, therefore, the state space is the subset:

$$E = \{ (x_1, x_2) \in \mathbb{N}^2 : 0 \le x_1, 0 \le x_2, x_1 + x_2 \le C \},$$
(1)

- $\lambda_1$ ,  $\lambda_2$ : arrival rates for PUs and SUs respectively (independent Poisson arrivals),
- *μ*<sub>1</sub>, *μ*<sub>2</sub>: service rates for PUs and SUs respectively (independent exponentially distributed service times),
- *a*(*x*<sub>1</sub>, *x*<sub>2</sub>): *E* → ℝ, admission decision function for SUs, and represents the probability that a SU that arrives starts being served when there are *x*<sub>1</sub> PUs and *x*<sub>2</sub> SUs.

Thus the stochastic process  $(X_1(t), X_2(t))$  has transition rates  $q((x_1, x_2), (x'_1, x'_2))$ , from state  $(x_1, x_2)$ to state  $(x'_1, x'_2)$ , defined by:

- $q((x_1, x_2), (x_1 + 1, x_2)) = \lambda_1$ , if  $x_1 + x_2 < C$ ,
- $q((x_1, x_2), (x_1 1, x_2)) = \mu_1 x_1,$
- $q((x_1, x_2), (x_1, x_2 + 1)) = a(x_1, x_2)\lambda_2$ , if  $x_1 + x_2 < C$ ,
- $q((x_1, x_2), (x_1, x_2 1)) = \mu_2 x_2,$ 
  - $q((x_1, x_2), (x_1 + 1, x_2 1)) = \lambda_1$ , if  $x_1 + x_2 = C$  and  $x_2 \neq 0$ .

Definition 2.2 (Free admission control policy). We call free admission control model when in the previous definition we consider no admission control policy, then  $a(x_1, x_2) = 1$  if  $x_1 + x_2 < C$  and  $a(x_1, x_2) = 0$  if  $x_1 + x_2 = C$ .

Definition 2.3 (Deterministic admission control policy). In the deterministic case  $a(x_1, x_2) \in \{0, 1\}$ ; if  $a(x_1, x_2) = 1$  and a SU arrives, it will start being served, and when  $a(x_1, x_2) = 0$ , it will not. In this work we assume  $x_1 + x_2 = \delta$ , with  $0 < \delta < C$ , as an admission control boundary. That is to say,  $a(x_1, x_2) = 1$  if  $x_1 + x_2 < \delta$  and  $a(x_1, x_2) = 0$  if  $x_1 + x_2 \ge \delta$ .

Definition 2.4 (Probabilistic admission control policy). In the probabilistic admission control SUs can access the system with a probability related with the number of users in the system. Let us assume that  $a(x_1, x_2)$  is a continuous function that vanishes close to the border  $\gamma = \{(x_1, x_2) : x_1 + x_2 = C\}$ . In this work we consider  $a(x_1, x_2) = 1 - (x_1 + x_2)/C$ .

<sup>192</sup> Concerning the above formulation we may make some remarks. First notice that PUs behave as <sup>193</sup> a M/M/C/C queue, independent of the behavior of the SUs and of the admission policy. Secondly, <sup>194</sup> in this work we consider two approaches for the admission control mechanisms: a deterministic <sup>195</sup> and a probabilistic one. Thirdly, it is important to highlight that in the case when  $\mu_1 = \mu_2$ , for some <sup>196</sup>

type of admission policies  $a(x_1, x_2)$ , the process is a one-dimensional CTMC and the stationary 197 distribution can be computed explicitly. However, when  $\mu_1 \neq \mu_2$  (which represents the natural 198 199 situation in cognitive radio networks) it is not possible to obtain a closed form expression of its stationary distribution (see for example [43] and the references therein). Finally, although in the 200 general case the stationary distribution can be computed numerically, our approach consists in 201 formulating the corresponding fluid limit in order to characterize the system behavior and study 202 the influence of the admission control decisions in a more feasible and efficient way. We infer 203 204 properties of the stochastic system from the study of fixed points of the deterministic fluid limit and the asymptotic distribution around it, and we define practical QoS criteria for sharing spectrum 205 policies. 206

### 3 FLUID MODEL

207

208

222 223 224

225

226

239

209 The Markovian structure of a process allows us to analyze its asymptotic behavior by means of a 210 simpler deterministic approximation: the fluid limit (generally obtained as a solution of an ODE). 211 Fluid limits have been used for particle systems, biology, epidemics, as well as in the study of 212 telecommunication networks. Generally speaking, starting from a stochastic model, the objective is to find a deterministic approximation for the original process. Whereas the stochastic process is a 213 214 microscopic description of the system, we can say that the corresponding differential equation gives 215 a macroscopic description that captures the main characteristics of the system. See for instance 216 classical results on convergence of Markov processes in [10, 12, 13, 33, 36].

As a very simplified description of the method, the proof of this approximation result is generally based on a martingale decomposition of the Markov process, which shows that the average behavior of the stochastic process is captured by the drift part while the stochastic fluctuation of second order (corresponding to the martingale) vanishes with the scaling and limit procedure. More specifically, consider a Markov process  $\tilde{X}^{N}(t)$  parametric in N and its martingale decomposition:

$$\widetilde{X}^{N}(t) = \widetilde{X}^{N}(0) + \int_{0}^{t} \widetilde{Q}^{N}(\widetilde{X}^{N}(s))ds + \widetilde{M}^{N}(t),$$

where  $\widetilde{Q}^{N}(l)$  is the so-called drift of the process at state l, which is calculated as  $\sum_{m \in S} (l-m)q(l,m)$ , being q(l,m) the transition rate from state l to m, S the state space, and where  $\widetilde{M}^{N}(t)$  is a martingale. Consider now the scaled process  $X^{N}(t) = \widetilde{X}^{N}(t)/N$ , then:

$$X^{N}(t) = X^{N}(0) + \frac{1}{N} \int_{0}^{t} \widetilde{Q}^{N}(\widetilde{X}^{N}(s)) ds + \frac{\widetilde{M}^{N}(t)}{N}.$$

If there exists a Lipschitz function *Q* such that:

$$\lim_{N \to \infty} \sup_{t \in [0,T]} \left\| \frac{\widetilde{Q}^N(\widetilde{X}^N(t))}{N} - Q(X^N(t)) \right\| = 0$$
(2)

in probability, where  $\|\cdot\|$  is the Euclidean norm, and  $\widetilde{M}^N(t)/N$  converges to zero in probability, then  $X^N(t)$  converges in probability over compact time intervals to a deterministic process x(t), described by the ODE:

$$x'(t) = Q(x(t)).$$
 (3)

The drift Q may be interpreted as the expected rate of change of the stochastic process (see Figure 1 for an illustration of this convergence in a toy example).

This introduces the problem of finding the suitable scale for the approximation. A typical scaling procedure consists in dividing the process by N and considering transition rates multiples of N; jumps are of order 1/N and transition rates are of order N, which means that the product remains or

Fig. 1. Illustration of a Markov process convergence. The continuous red line represents the solution of the ODE and the dashed blue one is a trajectory of  $X^{N}(t)$ .

tends to a constant as N increases. This is the scaling considered in this work, we refer to [18, 25, 33] as references for this and other scaling regimes, under which there are different limit results.

Let *N* be the scaling factor, and we define, as for the original model presented in Definition 2.1, the following sequence of CTMCs  $(\widetilde{X}_1^N, \widetilde{X}_2^N)$  and whose state space is:

$$\overline{E}^N = \{ (Ni, Nj) : (i, j) \in E \}$$

where *E* is defined in Equation (1).

Definition 3.1. Consider the sequence of CTMCs  $(\widetilde{X}_1^N, \widetilde{X}_2^N)$  defined as follows.

- $\widetilde{X}_1^N(t)$ ,  $\widetilde{X}_2^N(t)$ : number of PUs and SUs at time *t*, respectively,
- *CN*: total number of subchannels,
- $\lambda_1 N$ ,  $\lambda_2 N$ : arrival rates for PUs and SUs, respectively,
- $\mu_1, \mu_2$ : service rates for PUs and SUs, respectively,
- $\tilde{a}^N(x_1, x_2)$ : admission decision for SUs in each state.

The admission decision in each state should verify:

$$\lim_{N \to +\infty} \widetilde{a}^N(Nx_1, Nx_2) = a(x_1, x_2)$$

This scaling concerns both admission control schemes presented in Section 2. In the case of a deterministic admission control  $\tilde{a}^N(x_1, x_2) = 1$  if  $x_1 + x_2 < N\delta$  and  $\tilde{a}^N(x_1, x_2) = 0$  if  $x_1 + x_2 \ge N\delta$ . For the probabilistic admission control let  $\tilde{a}^N(x_1, x_2) = 1 - (x_1 + x_2)/CN$ .

The sequence of scaled stochastic process  $(\widetilde{X}_1^N(t), \widetilde{X}_2^N(t))$  has transition rates  $\widetilde{q}^N((x_1, x_2), (x'_1, x'_2))$ , from state  $(x_1, x_2)$  to state  $(x'_1, x'_2)$ , defined by:

•  $\widetilde{q}^N((x_1, x_2), (x_1 + 1, x_2)) = \lambda_1 N$ , if  $x_1 + x_2 < CN$ , •  $\tilde{q}^N((x_1, x_2), (x_1 - 1, x_2)) = \mu_1 x_1,$ 

- $\tilde{q}^N((x_1, x_2), (x_1, x_2 + 1)) = \tilde{a}^N(x_1 x_2)\lambda_2 N$ , if  $x_1 + x_2 < CN$ ,
- $\overline{q}^N((x_1, x_2), (x_1, x_2 1)) = \mu_2 x_2,$   $\overline{q}^N((x_1, x_2), (x_1 + 1, x_2 1)) = \lambda_1 N$ , if  $x_1 + x_2 = CN$  and  $x_2 \neq 0$ .

In Table 1 we summarize the scaled parameters and their relationship with the original ones.

In this scaling scheme we go from our original system in Section 2 to a system where arrival rates and capacity are multiplied by N, that can be interpreted as a large network, with many users (both PUs and SUs) and large capacity. On the other hand, service rates in each channel are not scaled,

QoS provision in a dynamic channel allocation based on admission control decisions

Table 1. Original and scaled parameters for the two-dimensional process  $(X_1, X_2)$  and  $(\widetilde{X}_1^N, \widetilde{X}_2^N)$ .

$(X_1, X_2)$	$\lambda_1$	$\lambda_2$	$\mu_1$	$\mu_2$	С	а
$(\widetilde{X}_1^N, \widetilde{X}_2^N)$	$\lambda_1 N$	$\lambda_2 N$	$\mu_1$	$\mu_2$	CN	$\widetilde{a}^N$

as for instance they depend on the service type, and they do not increases individually, despite the total service time increases with the number of users as  $\mu_1 \widetilde{X}_1^N(t)$  for PUs and  $\mu_2 \widetilde{X}_2^N(t)$  for SUs. Finally the admission control in the large system depends only on the proportion of resources occupied.

We consider now the scaled process  $(X_1^N, X_2^N)$ , defined by

$$(X_1^N, X_2^N) = (\widetilde{X}_1^N, \widetilde{X}_2^N)/N \tag{4}$$

and whose state space is:

 $E^N = \{(i/N, j/N) : (i, j) \in E\}$ 

where *E* is defined in Equation (1).

This scaled process will converge to the deterministic fluid limit. In order to state the fluid limit result we verify that our process satisfies equation (2). We compute the drift in the following proposition.

**PROPOSITION 3.2.** The drift for the process stated in Definition 2.1 is

$$Q(x_1, x_2) = \begin{pmatrix} \lambda_1 - \mu_1 x_1 \\ \lambda_2 a(x_1, x_2) - \mu_2 x_2 \end{pmatrix}, if x_1 + x_2 > C;$$

$$Q(x_1, x_2) = \begin{pmatrix} \lambda_1 - \mu_1 x_1 \\ -\lambda_1 - \mu_2 x_2 \end{pmatrix}, if x_1 + x_2 = C, x_2 > 0;$$
  
$$Q(x_1, x_2) = \begin{pmatrix} -\mu_1 x_1 \\ 0 \end{pmatrix}, if(x_1, x_2) = (C, 0).$$

The drift  $\widetilde{O}^N(x_1, x_2)$  for the corresponding scaled process presented in Definition 3.1 verifies

$$\frac{1}{2} \sum_{n=1}^{N} \left( \widetilde{\mathbf{x}}^{n} \cdot \widetilde{\mathbf{x}}^{n} \right) = \left( \left( \mathbf{x}^{n} \cdot \mathbf{x}^{n} \right) \right)$$

$$\lim_{N \to +\infty} \frac{1}{N} Q^N \left( X_1^N, X_2^N \right) = Q \left( X_1^N, X_2^N \right)$$

**PROOF.** We compute the drift of  $(X_1, X_2)$  defined as:

$$Q(x_1, x_2) = \sum_{(x_1', x_2') \in E} q((x_1, x_2), (x_1', x_2')) \left[ (x_1', x_2') - (x_1, x_2) \right].$$

$$Q(x_1, x_2) = \lambda_1 \begin{pmatrix} 1 \\ 0 \end{pmatrix} + a(x_1, x_2)\lambda_2 \begin{pmatrix} 0 \\ 1 \end{pmatrix} + \mu_1 x_1 \begin{pmatrix} -1 \\ 0 \end{pmatrix} + \mu_2 x_2 \begin{pmatrix} 0 \\ -1 \end{pmatrix}, \text{ if } x_1 + x_2 < NC,$$

$$Q(x_1, x_2) = \lambda_1 \begin{pmatrix} 1 \\ -1 \end{pmatrix} + \mu_1 x_1 \begin{pmatrix} -1 \\ 0 \end{pmatrix} + \mu_2 x_2 \begin{pmatrix} 0 \\ -1 \end{pmatrix}, \text{ if } x_1 + x_2 = C \text{ and } x_2 > 0,$$

$$Q(x_1, 0) = \mu_1 x_1 \begin{pmatrix} -1 \\ 0 \end{pmatrix}$$
, if  $x_1 = C$  and  $x_2 = 0$ 

We compute the drift of  $(\widetilde{X}_1^N, \widetilde{X}_2^N)$  defined as:

$$\widetilde{Q}^N(x_1, x_2) = \sum_{(x_1', x_2') \in \widetilde{E}^N} \widetilde{q}^N((x_1, x_2), (x_1', x_2')) \left[ (x_1', x_2') - (x_1, x_2) \right].$$

$$\widetilde{Q}^{N}(x_{1}, x_{2}) = N\lambda_{1} \begin{pmatrix} 1\\0 \end{pmatrix} + \widetilde{a}^{N}(x_{1}, x_{2})N\lambda_{2} \begin{pmatrix} 0\\1 \end{pmatrix} + \mu_{1}x_{1} \begin{pmatrix} -1\\0 \end{pmatrix} + \mu_{2}x_{2} \begin{pmatrix} 0\\-1 \end{pmatrix}, \text{ if } x_{1} + x_{2} < NC,$$

$$\widetilde{Q}^{N}(x_{1}, x_{2}) = N\lambda_{1} \begin{pmatrix} 1 \\ -1 \end{pmatrix} + \mu_{1}x_{1} \begin{pmatrix} -1 \\ 0 \end{pmatrix} + \mu_{2}x_{2} \begin{pmatrix} 0 \\ -1 \end{pmatrix}, \text{ if } x_{1} + x_{2} = NC \text{ and } x_{2} > 0,$$

$$\widetilde{Q}^{N}(x_{1}, x_{2}) = (1 - 1) + (1 - 1)$$

$$\widetilde{Q}^N(x_1,0) = \mu_1 x_1 \begin{pmatrix} -1 \\ 0 \end{pmatrix}$$
, if  $x_1 = NC$  and  $x_2 = 0$ .

Then we replace  $(x_1, x_2)$  by  $(Nx_1, Nx_2)$  in the previous equations and divide by N. We need that  $\lim_{N\to+\infty} \tilde{a}^N(Nx_1, Nx_2) = a(x_1, x_2)$ , in fact we have that  $\tilde{a}^N(Nx_1, Nx_2) = a(x_1, x_2)$  for the three different admission control schemes presented in Section 2. According to this we can conclude that

$$\lim_{N \to +\infty} \frac{1}{N} \widetilde{Q}^N \left( \widetilde{X}_1^N, \widetilde{X}_2^N \right) = Q \left( X_1^N, X_2^N \right).$$

Classical results on convergence of Markov processes assume some regularity properties of the fluid ODE, i.e. the vector field  $Q(x_1, x_2)$  defining the ODE must be a Lipschitz continuous function in the domain of interest. It is a sufficient condition for existence and uniqueness of solutions given initial conditions. In our system this regularity condition does not always hold. In this context, using results obtained by Bortolussi in [7, 9], it is possible to determine a PWSDS that is the fluid limit.

The rest of the paper is structured as follows. In Subsection 3.1 we introduce some results from [7, 9] and other references. Then, as a first step we analyze in Subsection 3.2 the system without an admission control policy (free admission control policy). In Subsection 3.3 we continue with the characterization of the system considering a deterministic admission control and finally in Subsection 3.4 we study a probabilistic admission control policy. In all cases we analyze, together with the fluid limit, the fixed points for the deterministic approximation and the asymptotic distribution, all with the objective of designing practical admission control algorithms.

#### 3.1 **Piecewise smooth approximation**

In the case where the drift is discontinuous the fluid limit can be obtained in the framework of differential equations with discontinuous right-hand side [15]. In this context the differential equation is replaced by what is called a differential inclusion, this means that Equation (3) is replaced by

$$x'(t) \in \overline{Q}(x(t)) \tag{5}$$

where Q is a set-valued mapping known as Filippov extension of Q defined as the convex hull of the accumulation points of the drift. We define a Filippov solution as an absolutely continuous function x(t) such that  $x(0) = x_0$  and  $x'(t) \in \overline{Q}(x(t))$  almost everywhere. We refer to [7, 16] and references therein for a more detailed exposition.

Concretely, considering  $x'(t) = Q(x), Q : E \to \mathbb{R}^2, E \subseteq \mathbb{R}^2, \bigcup R_i \supseteq E(R_i \ i = 1, 2 \text{ is a set of}$ disjoint regions), where Q is smooth on  $R_i$  and can be discontinuous only on the boundaries of  $R_i$ , and restricting our attention to our two different problems we have:

- Free admission control and probabilistic admission control policies: we only have one region 389  $(R_1)$  and its border y. We have  $Q_1(x)$  and  $Q_2(x)$  the velocity vectors, both smooth in  $R_1 = \{x :$ 390 h(x) < 0 and  $\gamma = \{x : h(x) = 0\}$  respectively with h(x) smooth such that  $\nabla h(x) \neq 0$  in  $\gamma$ .

427 428 Then  $x'(t) \in \overline{Q}(x(t))$  with:

$$\overline{Q}(x) = \begin{cases} Q_1(x) & \text{if } x \in R_1 \\ conv(Q_1, Q_2) & \text{if } x \in \gamma \end{cases}$$

• Deterministic admission control policies: we have a system with two regions  $(R_1, R_2)$  and the boundary between them  $(\gamma')$ . Let  $Q_1(x)$  and  $Q_2(x)$  be continuous in  $R_1 = \{x : h(x) < 0\}$  and  $R_2 = \{x : h(x) > 0\}$  respectively and  $\gamma' = \{x : h(x) = 0\}$  with h(x) a smooth function with  $\nabla h(x) \neq 0$  in  $\gamma'$ .) Then  $x'(t) \in \overline{Q}(x(t))$  with:

$$\overline{Q}(x) = \begin{cases} Q_1(x) & \text{if } x \in R_1 \\ conv(Q_1, Q_2) & \text{if } x \in \gamma' \\ Q_2(x) & \text{if } x \in R_2 \end{cases}$$

where  $conv(Q_1, Q_2)$  is the convex hull of the vectors  $\{Q_1, Q_2\}$ . Notice that for each continuity point *x* of Q,  $\overline{Q}(x) = \{Q(x)\}$ , so that we have a proper differential inclusion only in the discontinuity region (the borders  $\gamma$  or  $\gamma'$ ).

Filippov proved results about existence and uniqueness of solutions [15]. If  $Q_1$  and  $Q_2$  are  $C^1$ ,  $Q_1 - Q_2$  is  $C^1$  in  $\gamma$  (or  $\gamma'$  as appropriate), h is  $C^2$  in  $\gamma$  (or  $\gamma'$ ) and at least one of  $n^T(x)Q_1(x) > 0$  or  $n^T(x)Q_2(x) < 0$  holds, with x on the border  $\gamma$  (or  $\gamma'$ ) and n(x) the normal vector to the border, then there exists a unique Filippov solution from each initial condition. Considering x on the border  $\gamma'$ (or  $\gamma$ ), there are different behaviors of a solution starting in x depending on the value of  $n^T(x)Q_1(x)$ and  $n^T(x)Q_2(x)$ :

- transversal crossing: if  $n^T(x)Q_1(x)$  and  $n^T(x)Q_2(x)$  have the same sign, e.g. if  $n^T(x)Q_1(x) > 0$ and  $n^T(x)Q_2(x) > 0$ , a solution starting in  $R_1$  crosses the border and stays in  $R_2$ ;
- sliding motion: if  $(n^T(x)Q_1(x))(n^T(x)Q_2(x)) < 0$  there is sliding motion, there are two cases: unstable sliding motion when  $n^T(x)Q_1(x) < 0$  and  $n^T(x)Q_2(x) > 0$  (in this case there is no uniqueness for solutions) and stable sliding motion when  $n^T(x)Q_1(x) > 0$  and  $n^T(x)Q_2(x) < 0$ . In this last case, that is ours, the system cannot escape from the border, then the solution follows a vector field obtained as convex combination of  $Q_1$  and  $Q_2$ , obtaining a new vector field  $g(x) = (1 - \alpha(x))Q_1 + \alpha(x)Q_2$  with  $\alpha(x) \in [0, 1]$  that verifies  $n^T(x)g(x) = 0$ ;
  - tangential crossing: if  $n^T(x)Q_1(x) = 0$  (or  $n^T(x)Q_2(x) = 0$ ), then the trajectory continues in the region pointed by the non-zero vector field.

In our context, in all cases (free, deterministic and probabilistic admission control) we have a discontinuous drift that leads to a differential equations with discontinuous right-hand side and to the presence of sliding motion, as we show in the following subsections.

#### 3.2 Free admission control policy

In this subsection we assume that  $a(x_1, x_2) = 1$  for all  $(x_1, x_2) \in R_1$  such that  $R_1 = \{(x_1, x_2) : x_1 + x_2 - C < 0\}$ , 0 otherwise. The goal is to study the behavior of the system without any intervention: if a SU arrives and there is at least one idle subchannel, the SU will be served. Here we have discontinuous transition rates, as in the border of the state space  $\gamma = \{(x_1, x_2) : x_1 + x_2 - C = 0\}$ we have  $a(x_1, x_2) = 0$ . As we explained, these discontinuities lead to a deterministic limit whose trajectories are continuous but not differentiable. Because of this, some trajectories present sliding motion.

<sup>437</sup> PROPOSITION 3.3. Let  $Q_1(x_1, x_2)$  and  $Q_2(x_1, x_2)$  be vector fields, both smooth in  $R_1$  and  $\gamma$  respectively <sup>438</sup> such that

$$Q_1(x_1, x_2) = \begin{pmatrix} \lambda_1 - \mu_1 x_1 \\ \lambda_2 - \mu_2 x_2 \end{pmatrix}, \qquad Q_2(x_1, x_2) = \begin{pmatrix} \lambda_1 - \mu_1 x_1 \\ -\lambda_1 - \mu_2 x_2 \end{pmatrix},$$

441

and let  $n(x_1, x_2)$  be the normal vector to the boundary  $\gamma$  ( $n^T(x_1, x_2) = (1, 1)$  for all  $(x_1, x_2) \in \gamma$ ) then we have a PWSDS driven by the following equations.

444 If  $x_1 + x_2 < C$  or  $\lambda_1 + \lambda_2 \le \mu_1 x_1 + \mu_2 x_2$ :

$$\begin{cases} x_1' = \lambda_1 - \mu_1 x_1, \\ x_2' = \lambda_2 - \mu_2 x_2. \end{cases}$$

*if*  $x_1 + x_2 = C$  *and*  $\lambda_1 + \lambda_2 > \mu_1 x_1 + \mu_2 x_2$ *:* 

$$\begin{cases} x_1' = \lambda_1 - \mu_1 x_1, \\ x_2' = -\lambda_1 + \mu_1 x_1. \end{cases}$$

and if  $x_1 = C$ :

453  
454  
455  
$$\begin{cases} x'_1 = -\mu_1 x_1, \\ x'_2 = 0. \end{cases}$$

SKETCH OF THE PROOF. We have that  $n^T(x_1, x_2)Q_1(x_1, x_2) = 0 \Leftrightarrow \lambda_1 + \lambda_2 - \mu_1 x_1 - \mu_2 x_2 = 0$  and  $n^T(x_1, x_2)Q_2(x_1, x_2) = 0 \Leftrightarrow -\mu_1 x_1 - \mu_2 x_2 = 0$ . Then, for studying  $n^T(x_1, x_2)Q_i(x_1, x_2)$  we have several cases depending on the position of the line  $\lambda_1 + \lambda_2 - \mu_1 x_1 - \mu_2 x_2 = 0$ . It is clear that it depends on the values of  $\lambda_1$ ,  $\lambda_2$ ,  $\mu_1$  and  $\mu_2$ . In particular, we have that  $n^T(x_1, x_2)Q_1(x_1, x_2) > 0$  if  $\lambda_1 + \lambda_2 - \mu_1 x_1 - \mu_2 x_2 > 0$ ,  $Q_1$  and *n* are tangent in the points over the line  $\lambda_1 + \lambda_2 - \mu_1 x_1 - \mu_2 x_2 = 0$ and  $n^{T}(x_{1}, x_{2})Q_{1}(x_{1}, x_{2}) < 0$  if  $\lambda_{1} + \lambda_{2} - \mu_{1}x_{1} - \mu_{2}x_{2} < 0$ . On the other hand,  $n^{T}(x_{1}, x_{2})Q_{2}(x_{1}, x_{2}) < 0$ in y independently of the parameters  $\lambda_i$  and  $\mu_i$ . Because of this we are in the presence of sliding motion when  $-\mu_1 x_1 + \mu_2 x_2 < \lambda_1 + \lambda_2$  and  $x_1 + x_2 = C$ . In that case we define the differential inclusion by a convex combination  $g(x_1, x_2) = (1 - \alpha(x_1, x_2))Q_1 + \alpha(x_1, x_2)Q_2$  verifying  $n^T(x_1, x_2)g(x_1, x_2) = 0$ (the solution cannot escape from the border). Computing  $\alpha(x_1, x_2)$  we obtain

$$\alpha(x_1, x_2) = \frac{\mu_1 x_1 + \mu_2 x_2}{\lambda_1 + \lambda_2}$$

then substituting in  $g(x_1, x_2)$  the result is proved.

Let

$$(x_1(t), x_2(t))$$
 (6)

be the PWSDS that is the solution to the previous equations with initial condition ( $x_1(0), x_2(0)$ ), we describe the trajectories for different system parameters and initial conditions. Complementary to this, in Prop. 3.5 we study the fixed points.

The discussion depends on the existence or not of times where trajectories hit or leave the border  $\gamma$ . Those times are the solutions of the equations  $x_1(t) + x_2(t) - C = 0$  and  $\lambda_1 + \lambda_2 = \mu_1 x_1(t) + \mu_2 x_2(t)$  and can not always be computed explicitly.

- Case 1: If the initial condition (x<sub>1</sub>(0), x<sub>2</sub>(0)) satisfies x<sub>1</sub>(0) + x<sub>2</sub>(0) < C we have two subcases:</li>
  if ∄ t<sup>+</sup> > 0 such that x<sub>1</sub>(t<sup>+</sup>)+x<sub>2</sub>(t<sup>+</sup>)-C = 0, then the solution (x<sub>1</sub>(t), x<sub>2</sub>(t)) evolves according to Q<sub>1</sub>(x<sub>1</sub>, x<sub>2</sub>) remaining in R<sub>1</sub> and converges to its attractor fixed point (x<sub>1</sub><sup>\*</sup>, x<sub>2</sub><sup>\*</sup>). See Fig. 2 first row left. Note that the fixed point may also be on *γ*.
- if  $\exists t^+ > 0$  such that  $x_1(t^+) + x_2(t^+) C = 0$ , then the solution  $(x_1(t), x_2(t))$  evolves according to  $Q_1(x_1, x_2)$  remaining in  $R_1$  until it hits the border at  $t^+$ . Afterwards, the solution evolves according to

$$g(x_1, x_2) = \begin{cases} x_1' = \lambda_1 - \mu_1 x_1, \\ x_2' = -\lambda_1 + \mu_1 x_1. \end{cases}$$

and depending on the fixed point we have:

ACM Trans. Model. Perform. Eval. Comput. Syst., Vol. 1, No. 1, Article 1. Publication date: January 2019.

\* if the fixed point  $(x_1^*, x_2^*) \in R_1$ , always  $\exists t^{++}$ , an exit point, such that  $t^{++} > t^+ : \mu_1 x_1(t^{++}) + t^+$ 491  $\mu_2 x_2(t^{++}) = \lambda_1 + \lambda_2$ . Then for  $t > t^{++}$  the solution evolves according to  $Q_1(x_1, x_2)$  and 492 converges to  $(x_1^*, x_2^*)$ . See Fig. 2 second row left. 493 \* if the fixed point  $(x_1^*, x_2^*) \in \gamma$ , the solution remains in  $\gamma \forall t > t^+$ . See Fig. 2 second row 494 right. 495 • Case 2: If the initial condition  $(x_1(0), x_2(0))$  satisfies  $x_1(0) + x_2(0) = C$  (with  $x_2(0) > 0$ ) 496 - if  $\exists t^* > 0$  such that  $\mu_1 x_1(t^*) + \mu_2 x_2(t^*) = \lambda_1 + \lambda_2$ , the solution  $(x_1(t), x_2(t))$  evolves according 497 498 to  $q(x_1, x_2)$  (defined before) until  $t^*$  (an exit point) and then it evolves according to  $Q_1(x_1, x_2)$ . It converges to the fixed point  $(x_1^*, x_2^*) \in R_1$ . See Fig. 2 first row right. 499 - if  $\nexists t^* > 0$  such that  $\mu_1 x_1(t^*) + \mu_2 x_2(t^*) = \lambda_1 + \lambda_2$ , then 500 \* if  $(x_1^*, x_2^*) \in R_1, \forall t > 0$  the solution  $(x_1(t), x_2(t))$  evolves according to  $Q_1(x_1, x_2)$  remaining 501 in  $R_1$  and converges to  $(x_1^*, x_2^*)$ . See Fig. 2 third row left. 502 \* if  $(x_1^*, x_2^*) \in \gamma$ ,  $\forall t > 0$  the solution  $(x_1(t), x_2(t))$  evolves according to  $g(x_1, x_2)$  remaining 503 in  $\gamma$  and converges to  $(x_1^*, x_2^*)$ . See Fig. 2 third row right. 504 • Case 3: If the initial condition  $(x_1(0), x_2(0))$  satisfies  $x_1(0) = C$ : 505 - if  $\lambda_1/\mu_1 > C$ , the solution remains at (*C*, 0) being the fixed point. 506 - if  $\lambda_1/\mu_1 < C$ , the solution evolves like Case 2. 507 508 Next we present the fluid limits results. 509 THEOREM 3.4. Consider the process  $(\widetilde{X}_1^N, \widetilde{X}_2^N)$  with transition rates defined in Table 1, define: 510  $(X_{1}^{N}(t), X_{2}^{N}(t)) = (\widetilde{X}_{1}^{N}(t), \widetilde{X}_{2}^{N}(t))/N$ 511 512 and let  $(x_1, x_2)$  be the PWSDS defined in Equation (6) with initial condition  $(x_1(0), x_2(0))$ . If 513  $\lim_{N \to \infty} (X_1^N(0), X_2^N(0)) = (x_1(0), x_2(0))$ 514 515 then, for all T > 0, 516  $\lim_{N \to \infty} \sup_{t \in [0,T]} \left\| (X_1^N(t), X_2^N(t)) - (x_1(t), x_2(t)) \right\| = 0$ 517 518 in probability. 519 SKETCH OF THE PROOF. The proof follows straightforward from Theorem IV.2 in [7]. The hy-520 potheses of this Theorem are verified in our case; i.e. the scaling scheme of the process, as we 521 have defined in Section 3 and sumarized in Table 1, and the existence of a unique PWSDS with 522 523 regular trajectories, presented Subsection 3.2 in order to define Equation (6). Theorem IV.2 in [7] 524 considers two different regions  $R_1$  and  $R_2$  with a border between them, where the process and the PWSDS may change many times from one region to the other and there may be several different 525 pieces of sliding motion at the border. In our case we have only one region and the border, but 526 the proof in [7] is suitable for this case. More specifically, the proof there consists in splitting the 527

whole PWSDS trajectory in pieces in each region (where classical results, for example from [13], hold) and in sliding trajectories at the border. For that case the proof in [7] consists in replacing the discontinuous drift by the sliding vector field and prove convergence by an uniformization procedure. The proof of Lemma 3 in [8] that considers two different regions is valid for the case with a region and its border.

In our case, as we in fact have a switched linear system we only have one piece of sliding motion, and as our initial condition can only be in  $R_1$  we have three cases. In the first case the deterministic trajectory stays all the time in  $R_1$  and classical results hold. In the second case the trajectory starts in  $R_1$  and then presents sliding motion and stays at the border for  $t \rightarrow \infty$ . In the last case the trajectory PSWDS starts on  $R_1$  or at the border, then presents sliding motion and exits at the border, and then remains in  $R_1$ . In that case we need to check the exit conditions for the sliding motion,

Fig. 2. Different trajectories for the PWSDS defined in Proposition 3.3 with C = 1. First row (left) shows a trajectory in  $R_1$ , starting at (0.1, 0.1) ( $\lambda_1 = 2$ ,  $\lambda_2 = 1$ ,  $\mu_1 = 5$ ,  $\mu_2 = 4$ ). First row (right) shows a trajectory with initial condition (0.1, 0.9) at  $\gamma$ , with an exit point and that converges to the fixed point in  $R_1$  ( $\lambda_1 = 3$ ,  $\lambda_2 = 1.5$ ,  $\mu_1 = 6$ ,  $\mu_2 = 3.5$ ). The second row (left) shows a trajectory with initial condition (0.05, 0.9) at  $R_1$ , that stays for a while on  $\gamma$  and finally converges to the fixed point ( $\lambda_1 = 3$ ,  $\lambda_2 = 1.5$ ,  $\mu_1 = 6$ ,  $\mu_2 = 3.5$ ) and (right) a trajectory with initial condition (0.0) in  $R_1$  which finally remains on  $\gamma$  ( $\lambda_1 = 2$ ,  $\lambda_2 = 4$ ,  $\mu_1 = 4$ ,  $\mu_2 = 5$ ). The third row shows trajectories with initial condition (0.9, 0.1) at  $\gamma$ : (left) the whole trajectory for t > 0 in  $R_1$  ( $\lambda_1 = 2$ ,  $\lambda_2 = 1$ ,  $\mu_1 = 5$ ,  $\mu_2 = 4$ ) and (right) trajectory on  $\gamma \forall t > 0$  ( $\lambda_1 = 2$ ,  $\lambda_2 = 4$ ,  $\mu_1 = 4$ ,  $\mu_2 = 5$ .)

that are guaranteed because both vector fields are not tangential to the border at the same time (let us recall that  $Q_2$  always points towards  $R_1$ ).

An alternative approach can be done following [36]. In Chapter 8 the authors define what they call flat boundary process, that is a Markov process where transitions at the border are different from transitions in the interior of the state space, and transition rates are discontinuous at the border. Under some regularity conditions the authors of [36] obtained very similar results than [7]: they prove existence and uniqueness for the solution of the PWSDS and they prove convergence to such systems. In their presentation the coefficients of the convex combination defining the sliding vector field have a probabilistic interpretation. They consider a process with three coordinates, where the first two correspond to PUs and SUs as ours, and the third, valued 0 or 1 indicates if the system is at the border or not. With the same scaling as ours the third coordinate tends to 0 when 

ACM Trans. Model. Perform. Eval. Comput. Syst., Vol. 1, No. 1, Article 1. Publication date: January 2019.

QoS provision in a dynamic channel allocation based on admission control decisions

scaled. In addition, as transition rates in the interior are smooth, while process stays in the interior 589 the scaled process (dividing by *N*) changes a little. On the other hand, the number of jumps from 590 591 the interior to the border per time unit increases with N, so the third coordinate that indicates where the process is reaches its invariant distribution before the number of PUs and SUs. In that 592 interpretation the coefficient  $\alpha$  is the probability or the proportion of time that the process spends 593 at the border and  $(1 - \alpha)$  the the proportion of time that the process spends in the interior. 594

For further work concerning fluid limits, including systems with discontinuous rates we also refer to [9, 16, 22].

In the context of fluid limits it is usual to infer from the fixed point analysis of the deterministic system the behavior of the stochastic one in the stationary regime. If there is a unique fixed point that is a global attractor, the stochastic invariant distributions converges in probability to this fixed point [4, 24, 37]. In what follows we will exploit this general result.

**PROPOSITION 3.5.** Considering  $a(x_1, x_2) = 1$  for all  $(x_1, x_2) : x_1 + x_2 < C$ , and 0 otherwise, letting  $R_1$  and  $\gamma$  be the above defined zone and border and setting  $(x_1^*, x_2^*)$  as the PWSDS fixed point, then:

a. If  $\frac{\lambda_1}{\mu_1} + \frac{\lambda_2}{\mu_2} < C$ , then the fixed point  $(x_1^*, x_2^*) = \left(\frac{\lambda_1}{\mu_1}, \frac{\lambda_2}{\mu_2}\right) \in R_1$  and the mean system utilization is  $\frac{\lambda_1}{\mu_1} + \frac{\lambda_2}{\mu_2}$  (sub-critical case).

b. If λ₁/μ₁ + λ₂/μ₂ ≥ C and λ₁/μ₁ < C, then the fixed point (x₁\*, x₂\*) = (λ₁/μ₁, C - λ₁/μ₁) ∈ γ and the mean system utilization is C (critical case).</li>
c. If λ₁/μ₁ ≥ C, then the fixed point (x₁\*, x₂\*) = (C, 0) ∈ γ and the mean system utilization is C (critical case).

case).

SKETCH OF THE PROOF. Let  $Q_1$  and  $Q_2$  be the velocity vectors, both continuous in  $R_1$  and  $\gamma$ respectively:

$$Q_1(x_1, x_2) = \begin{pmatrix} \lambda_1 - \mu_1 x_1 \\ \lambda_2 - \mu_2 x_2 \end{pmatrix}, Q_2(x_1, x_2) = \begin{pmatrix} \lambda_1 - \mu_1 x_1 \\ -\lambda_1 - \mu_2 x_2 \end{pmatrix},$$

and let  $n(x_1, x_2)$  be a normal vector to the line  $\gamma = \{(x_1, x_2) : x_1 + x_2 = C\}$ , so that  $n^T(x_1, x_2)$  is 618 619 collinear with (1, 1) for all  $(x_1, x_2) \in \gamma$ .

620 As it is explained in Subsection 3.1, when summarizing the different possible behaviors of 621 both vector fields we have that all possible cases, for different values of the parameters, can be 622 categorized into two groups represented by Case 1 and Case 2 from Figure 3. In that figure the 623 solid line represents  $\gamma$ , the dotted line is  $\lambda_1 + \lambda_2 - \mu_1 x_1 - \mu_2 x_2 = 0$  and the vectors are  $Q_1$  and  $Q_2$ . In Case 1 the PWSDS fixed point is in  $R_1$  (Proposition 3.5.a); we call it sub-critical case. It is 624 easy to note that  $(x_1^*, x_2^*) = (\lambda_1/\mu_1, \lambda_2/\mu_2)$ . On the other hand, in Case 2, the fixed point is on  $\gamma$ 625 626 and its value is  $(x_1^*, x_2^*) = (\lambda_1/\mu_1, C - \lambda_1/\mu_1)$  representing a critical case, (Proposition 3.5.b). When 627  $\lambda_1/\mu_1 + \lambda_2/\mu_2 \ge C$  we can identify a sliding motion behavior near the fixed point, more precisely 628 we can affirm that the equation solution will live on  $\gamma$  most of the time. Both examples of Figure 3 629 consider  $\lambda_1/\mu_1 < C$ . Finally, when the system is saturated by PUs ( $\lambda_1/\mu_1 \ge C$ ), as a corollary from 630 Proposition 3.5.b the fixed point is  $(x_1^*, x_2^*) = (C, 0)$  (Proposition 3.5.c). 631

In Figures 4 and 5 we show the deterministic approximation and a trajectory of the stochastic 632 processes for the Cases 1 and 2 of Figure 3. In each one, in the left graphic we show the simulation 633 of one trajectory of the scaled Markov process and the PWSDS. In the right we show for the same 634 simulation the evolution on the plane of the Markov chain and the corresponding PWSDS. In 635 Figure 4 the fixed point is in  $R_1$  and in Figure 5 it is on  $\gamma$ . It is important to note that in both cases, 636 637

Fig. 3. Vector field for Case 1 (left): C = 1,  $\lambda_1 = 2$ ,  $\lambda_2 = 1$ ,  $\mu_1 = 5$ ,  $\mu_2 = 4$  and Case 2 (right): C = 1,  $\lambda_1 = 2$ ,  $\lambda_2 = 4, \mu_1 = 4, \mu_2 = 5$ . The solid line represents  $\gamma$  and the dotted line is  $\lambda_1 + \lambda_2 - \mu_1 x_1 - \mu_2 x_2 = 0$ . The region  $R_1$  is defined by  $R_1 = \{(x_1, x_2) : x_1 + x_2 < 1\}.$ 

Fig. 4. Case 1 with parameters: N = 100, C = 1,  $\lambda_1 = 2$ ,  $\lambda_2 = 1$ ,  $\mu_1 = 5$  and  $\mu_2 = 4$ . The PWSDS fixed point is  $(x_1^*, x_2^*) = (\lambda_1/\mu_1, \lambda_2/\mu_2) = (2/5, 1/4).$ 

for large time values, the scaled number of users in the stochastic process is around the PWSDS fixed point  $(x_1^*, x_2^*)$ .

Recalling the description of the system, if  $x_1 + x_2 = C$  and a PU arrives, a SU will be immediately deallocated giving the subchannel to the new PU. In this case, the QoS perceived by the SU will be affected because of the interruption of its communication. We are interested in SUs whose service cannot be interrupted with high probability (like a phone call or other interactive services). With this in mind, we can relate the interruption probability with the probability that the process lives on  $\gamma$ . We can conclude that the PWSDS fixed point has to be far enough from  $\gamma$  to avoid a strong impact on secondary communications. However, it has to be as close as possible to  $\gamma$  to permit 

Fig. 5. Case 2 with parameters:  $N = 100, C = 1, \lambda_1 = 2, \lambda_2 = 4, \mu_1 = 4$  and  $\mu_2 = 5$ . The PWSDS fixed point is  $(x_1^*, x_2^*) = (\lambda_1/\mu_1, C - \lambda_1/\mu_1) = (1/2, 1/2).$ 

more spectrum utilization and a high access probability for SUs. According to Proposition 3.5 and 706 observing Figures 4 and 5 we can identify two cases: when the PWSDS fixed point is in  $R_1$  and 707 when it is on  $\gamma$ . For the last one, the system in stationary regime works near  $\gamma$ , so the probability of 708 service interruption is too large. Then, the question in this case is how can we move the fixed-point? 709 The analysis in the subsections 3.3 and 3.4 will be concentrated on answering that question. In 710 particular we move the fixed point using admission control decisions. On the other hand, in the next 711 two subsections we concentrate in cases like Case 1 (when the PWSDS fixed point is in  $R_1$ ). More 712 specifically, we concentrate our efforts on answering the question: is the fixed point far enough 713 from *y* to assure a small interruption probability? 714

We study the interruption probability by means of the probability that the system is full  $P(X_1 +$ 715  $X_2 = C$ ). Both probabilities are highly related by 716

$$P(\text{deallocate a SU}) + P(\text{block a PU}) = P(X_1 + X_2 = C|\text{PU arrives}),$$

by PASTA property (Poisson Arrivals See Time Averages) the last probability is  $P(X_1 + X_2 = C)$ and *P*(block a PU) is the blocking probability for a M/M/C/C queue.

Gaussian asymptotic distribution in sub-critical cases. Another issue studied in the context of 3.2.1 fluid limits is the velocity of this convergence by looking at the fluctuations of the process around the limit. We refer to [13, 18, 33, 36] for the analysis of different scaling regimes and limit theorems in that sense, concerning different kinds of limit distributions.

If we consider cases when  $\lambda_1/\mu_1 + \lambda_2/\mu_2 < C$  and the PWSDS trajectory remains all the time 726 in  $R_1$ , it is possible to apply known results (see Theorem 2.3 of Chapter 11 in [13]) in order to obtain the asymptotic distribution. Let  $(x_1, x_2)$  be the trajectory of the PWSDS with initial condition 728  $(x_1(0), x_2(0))$ . If:

$$\lim_{N \to +\infty} \sqrt{N} [(X_1^N(0), X_2^N(0)) - (x_1(0), x_2(0))] = \chi(0)$$

 $\sqrt{N}[(X_1^N, X_2^N) - (x_1, x_2)] \Rightarrow \chi,$ 

732 with  $\chi(0)$  deterministic, then:

702

703 704 705

717 718 719

720

721

722

723

724

725

727

where  $(\chi(t))$  is a two-dimensional Gaussian process and  $\Rightarrow$  means convergence in distribution. ( $\chi(t)$ ) has a covariance matrix determined explicitly by:

$$Cov(\chi(t), \chi(r)) = \int_0^{t \wedge r} e^{A(t-s)} G(x_1(s), x_2(s)) e^{A(r-s)} ds$$

where  $A = \begin{pmatrix} -\mu_1 & 0\\ 0 & -\mu_2 \end{pmatrix}$  and  $G(x_1(s), x_2(s)) = \begin{pmatrix} \lambda_1 + \mu_1 x_1(s) & 0\\ 0 & \lambda_2 + \mu_2 x_2(s) \end{pmatrix}$ . In sub-critical cases, we can conclude that  $\lim_{N \to +\infty} P(X_1^N(t) + X_2^N(t) = C) = 0$  for all *t*. However,

In sub-critical cases, we can conclude that  $\lim_{N \to +\infty} P(X_1^N(t) + X_2^N(t) = C) = 0$  for all *t*. However, considering the defined Gaussian process and a finite large *N* we can present a practical criterion to analyze if the PWSDS fixed point is far enough from  $\gamma$ . In particular, we can obtain confidence bounds and also infer an adequate number of subchannels in order to avoid a high interruption probability for SUs.

3.2.2 Practical QoS design criterion in sub-critical cases. As we have shown in the simulated exam-749 ples of Figures 4 and 5, the fluid limit is an accurate approximation when N is large. Then, in practice, 750 a possible criterion to determine whether the PWSDS fixed point is far enough from  $\gamma$  would be to 751 consider a certain confidence region of  $(X_1^N(t), X_2^N(t))$  assuming a large value of t. If the resulting 752 confidence ellipse is entirely inside  $R_1$ , high probability of non-interruption is guaranteed. Otherwise, 753 we should try to move the fixed point. In particular we consider  $\lim_{t \to +\infty} G(x_1(s), x_2(s)) = G(x_1^*, x_2^*)$ 754 and define this limit matrix as  $G(\infty) = G(x_1^*, x_2^*)$ . Then, following the development in [29] we can 755 obtain the covariance matrix  $\Sigma(\infty)$  by solving: 756

$$A\Sigma(\infty) + \Sigma(\infty)A^T = -G(\infty).$$
<sup>(7)</sup>

Considering a fixed relation between both classes  $\frac{\lambda_1/\mu_1}{\lambda_2/\mu_2} = constant$ , using the deterministic confidence ellipse we can infer which is the ideal scaling parameter. In other words, we can obtain an 759 760 idea of the optimal number of resources (subchannels) necessary to guarantee a small interruption 761 probability for SUs. In Figure 6 we show the theoretical 95% confidence ellipses considering different 762 values of N for two different parameter sets (Case A and Case B). In particular, we have considered 763 C = 1, then N represents the number of channels of the system  $(\widetilde{X}_1^N(t), \widetilde{X}_2^N(t))$ . For Case A, (with  $C = 1, \lambda_1 = 9, \lambda_2 = 13, \mu_1 = 50$  and  $\mu_2 = 20$ ) we have that the ellipse is tangent to  $\gamma$  when 764 765 N = 180. Therefore, we can conclude that an admission control does not make sense in the system 766  $(\widetilde{X}_1^N(t), \widetilde{X}_2^N(t))$  when  $N \ge 180$ . In Table 2 we confirm that the interruption probability of SUs can 767 be analyzed studying the probability that the system is full of users (blocking probability of PUs 768 can be approximated by 0). For Case B (with C = 1,  $\lambda_1 = 10$ ,  $\lambda_2 = 12$ ,  $\mu_1 = 25$  and  $\mu_2 = 30$ ), we have 769 an analogous conclusion when  $N \ge 120$ . 770

Table 2. Values of full system probability and blocking PU probability for Case A of Figure 6.  $P(\tilde{X}_1^N(t) + \tilde{X}_2^N(t) > C)$  is approximated by a Gaussian distribution.

Ν	100	110	120	130	140	150

#### 3.3 Deterministic admission control policy

In this subsection we analyze the system when a deterministic admission control is applied. In this situation we consider  $\gamma' = \{(x_1, x_2) : x_1 + x_2 = \delta\}$  as the admission control border, then the question is: what is a reasonable value of  $\delta$  to guarantee certain level of QoS to SUs?

Fig. 6. Theoretical 95% confidence ellipses of  $(X_1^N(t), X_2^N(t))$ , considering different N values  $(N = 100, 120, 140, 160, \dots, 500)$ . Parameters of Case A: C = 1,  $\lambda_1 = 9$ ,  $\lambda_2 = 13$ ,  $\mu_1 = 50$  and  $\mu_2 = 20$ . Parameters of Case B: C = 1,  $\lambda_1 = 10$ ,  $\lambda_2 = 12$ ,  $\mu_1 = 25$  and  $\mu_2 = 30$ .

In this case the fluid limit is obtained in the same way as in Subsection 3.2, but the sliding motion occurs in  $\gamma'$ .

PROPOSITION 3.6. Let  $Q_1(x_1, x_2)$  and  $Q_2(x_1, x_2)$  be vector fields, both smooth in  $R_1 = \{(x_1, x_2) : x_1 + x_2 - \delta < 0\}$  and  $R_2 = \{(x_1, x_2) : x_1 + x_2 - \delta > 0\}$  respectively such that

$$Q_1(x_1, x_2) = \begin{pmatrix} \lambda_1 - \mu_1 x_1 \\ \lambda_2 - \mu_2 x_2 \end{pmatrix}, \qquad Q_2(x_1, x_2) = \begin{pmatrix} \lambda_1 - \mu_1 x_1 \\ -\mu_2 x_2 \end{pmatrix},$$

and let  $n(x_1, x_2)$  be the normal vector to the boundary  $\gamma'(n^T(x_1, x_2) = (1, 1)$  for all  $(x_1, x_2) \in \gamma')$  then we have a PWSDS driven by the following equations.

If  $x_1 + x_2 < \delta$ :

$$\begin{cases} x_1' = \lambda_1 - \mu_1 x_1, \\ x_2' = \lambda_2 - \mu_2 x_2. \end{cases}$$
  
else, if  $x_1 + x_2 - \delta = 0$  ( $\gamma'$ ):  
$$\begin{cases} x_1' = \lambda_1 - \mu_1 x_1, \\ x_2' = -\lambda_1 + \mu_1 x_1. \end{cases}$$
  
and if  $x_1 + x_2 > \delta$ :  
$$\begin{cases} x_1' = \lambda_1 - \mu_1 x_1, \\ x_2' = -\mu_2 x_2. \end{cases}$$
  
Notice that we consider the case  $\frac{\lambda_1}{\mu_1} < C$  because its practical importance.

The behavior is very similar as in the free admission control case, and we can think in this case as a sort of translation of the free case where the border that presents sliding motion is shifted from  $\gamma$  to  $\gamma'$ . Then, the proof is totally analogous to Proposition 3.3.

A convergence theorem analogous to Theorem 3.4 holds, in this case using directly Theorem IV.2 in [7], as for the deterministic policy there are two regions  $R'_1 = \{(x_1, x_2) : x_1 + x_2 < \delta\}$ ,  $R'_2 = \{(x_1, x_2) : x_1 + x_2 > \delta\}$ , and the border  $\gamma' = \{(x_1, x_2) : x_1 + x_2 = \delta\}$ , where the drift is discontinuous.

Claudina Rattaro, Laura Aspirot, Ernesto Mordecki, and Pablo Belzarena

In addition we can study fixed points, by an analysis similar to Proposition 3.5. However, the fixed point of the PWSDS in the most interesting cases lies in  $\gamma'$ . This fact hinders the development of a design criterion like in Subsection 3.2.2, as we do not have the same results for the asymptotic distribution.

In the deterministic policy scheme the hypotheses of Theorem 2.3 of Chapter 11 in [13] are not verified, due to the non-smoothness of the PWSDS at the border  $\gamma'$ .

We have convergence of the stationary regime to the PWSDS fixed point but there is not a
general framework that allows to state a Gaussian asymptotic distribution. Therefore, we proceed
to compute the asymptotic stationary distribution of the total number of users in the particular
case when service rates are the same for primary and secondary users.

The limitation to a particular case comes from our proof method that depends on the explicit stationary distribution, that can only be explicitly obtained for equal service rates. However, we will give some insight on the asymptotic distribution in this case, for different service rates, based on simulations. Further study of the general case is object of future work.

<sup>848</sup> Using the limit of the invariant distribution for the particular case, we can build some design <sup>849</sup> criteria in order to find an estimation of the optimal  $\delta$  value for certain maximum level of interruption <sup>850</sup> probability. We will show that the criteria can be extended to the case  $\mu_1 \neq \mu_2$  with good results in <sup>851</sup> 3.3.2.

*Non-Gaussian invariant distribution.* We consider the original system (when  $\mu_1 = \mu_2$ ) and 3.3.1 853 compute its invariant distribution, both for the original system and the scaled one. Then for the 854 scaled system that depends on N we find the limit of the invariant distribution when N goes to 855 infinity. For practical purposes as in this case, the invariant distribution can be computed explicitly. 856 There is no need to compute the asymptotic distribution, but theoretically we want to show that 857 the asymptotic distribution in the case where the equilibrium lies in the admission control border 858 is not Gaussian; with a different scaling, we find a geometric asymptotic distribution. The proof 859 is only in the particular case when service rates are the same for primary and secondary users, 860 that is when the problem is one-dimensional. The scaling, different from  $\sqrt{N}$ , and the geometric 861 distribution are not frequent in related works. 862

Consider the Markov chain defined in Section 2 with  $\mu_1 = \mu_2$  where the access control is defined considering  $\gamma'$ . In this case  $X = X_1 + X_2$  is a one dimensional Markov chain with state space  $E = \{0, 1, ..., C\}$ , and non-zero transition rates from *i* to *j*, q(i, j), given by:

$$q(i, i+1) = \begin{cases} \lambda_1 + \lambda_2 & \text{for } 0 \le i < \delta \\ \lambda_1 & \text{for } \delta \le i < C \end{cases}, \qquad q(i, i-1) = i\mu \text{ for } 0 < i \le C,$$

where  $\delta \in E$  denotes the border of the admission control, that is when we have  $\delta$  or more users we prohibit the access of new secondary users. Let us observe that in the general case described in Section 2 the total number of users  $X = X_1 + X_2$  is Markovian only if  $\mu_1 = \mu_2$ , so the reduction to a one dimensional Markov chain follows only in this case. In order to simplify notation in what follows let us call  $\nu_2 = \lambda_1 + \lambda_2$ , and  $\nu_1 = \lambda_1$ . We then have the following transition rates, where  $\nu_1 < \nu_2$ :

$$q(i, i+1) = \begin{cases} v_2 & \text{for } 0 \le i < \delta \\ v_1 & \text{for } \delta \le i < C \end{cases}, \qquad q(i, i-1) = i\mu \text{ for } 0 < i \le C,$$

We consider the scaled process  $\widetilde{X}^N = \widetilde{X}_1^N + \widetilde{X}_2^N$  with the scaling in Table 3. Theorem 3.4 holds in this case and we also have that  $X^N = \widetilde{X}^N/N$  converges in probability, uniformly over compact time intervals to *x*, given by the following equations, for  $0 \le \delta \le C$ .

### QoS provision in a dynamic channel allocation based on admission control decisions

1:19

explicitly compute the stationary distribution of X, and then for the scaled system  $\widetilde{X}^N$  for fixed N and obtain its limit when  $N \to \infty$ . X is a modification of a M/M/C/C queue, where the arrivals changes their rate depending on the number of clients in the queue. We will analyze our system as in [33] for the M/M/C/C queue. Computing the stationary distribution  $\pi$  for this Markov chain:

$$\begin{aligned} \pi(i)v_2 &= \pi(i+1)(i+1)\mu \text{ for } 0 \le i < \delta, \\ \pi(i)v_1 &= \pi(i+1)(i+1)\mu \text{ for } \delta \le i < C. \end{aligned}$$

932 Then,

933  
934  
935  
936  

$$\pi(i) = \frac{\rho_2^i}{i!}\pi(0) \quad \text{for} \quad 0 \le i \le \delta,$$
935  

$$\pi(i) = \left(\frac{\rho_2}{i!}\right)^{\delta} \frac{\rho_1^i}{\pi(0)} \quad \text{for} \quad \delta \le i \le C.$$

$$\pi(i) = \left(\frac{\rho_2}{\rho_1}\right)^o \frac{\rho_1^i}{i!} \pi(0) \quad \text{for} \quad \delta < i \le C,$$

where:

$$\pi(0)^{-1} = \sum_{i=0}^{\delta} \frac{\rho_2^i}{i!} + \left(\frac{\rho_2}{\rho_1}\right)^{\delta} \sum_{i=\delta+1}^{C} \frac{\rho_1^i}{i!}.$$

<sup>942</sup><sub>943</sub> The stationary distribution  $\tilde{\pi}^N$  for the process  $\tilde{X}^N$  is:

$$\sim_{N(c)} (N\rho_2)^i \sim_{N(c)} c$$

$$\widetilde{\pi}^{N}(i) = \frac{(NP_{2})}{i!} \widetilde{\pi}^{N}(0) \quad \text{for} \quad 0 \le i \le N\delta,$$
$$\widetilde{\pi}^{N}(i) = \frac{(P_{2})^{N\delta}}{(N\rho_{1})^{i}} \widetilde{\pi}^{N}(0) \quad f = N\delta,$$

$$\widetilde{\pi}^{N}(i) = \left(\frac{\rho_{2}}{\rho_{1}}\right)^{N \circ} \frac{(N\rho_{1})^{i}}{i!} \widetilde{\pi}^{N}(0) \quad \text{for} \quad N\delta < i \le C,$$

with:

$$\widetilde{\pi}^N(0)^{-1} = \sum_{i=0}^{N\delta} \frac{(N\rho_2)^i}{i!} + \left(\frac{\rho_2}{\rho_1}\right)^{N\delta} \sum_{i=N\delta+1}^{NC} \frac{(N\rho_1)^i}{i!}$$

THEOREM 3.7. Consider the original processes with equal service rates  $\mu_1 = \mu_2$  and  $X^N$  defined as before. Then, the stationary distribution of  $\tilde{X}^N - N\delta$  converges to the distribution of an integer variable Z given by

$$P(Z = j) = \begin{cases} \rho\left(\frac{\rho_2}{\delta}\right)^j & \text{if } j < 0, \\\\ \rho\left(\frac{\rho_1}{\delta}\right)^j & \text{if } j \ge 0, \end{cases}$$
where  $\rho_1 = \frac{\nu_1}{\mu}, \rho_2 = \frac{\nu_2}{\mu}, \rho = \left(\frac{\rho_1}{\delta - \rho_1} + \frac{\rho_2}{\rho_2 - \delta}\right)^{-1}.$ 

962 where 

PROOF. Let us compute, for  $0 \le k < N\delta$  the stationary distribution  $\tilde{\pi}^N(N\delta - k)$ . Computing its inverse:

$$\begin{split} \widetilde{\pi}^{N} (N\delta - k)^{-1} &= \frac{(N\delta - k)!}{(N\rho_{2})^{N\delta - k}} \widetilde{\pi}^{N} (0)^{-1} \\ &= \frac{(N\delta - k)!}{(N\rho_{2})^{N\delta - k}} \left( \sum_{i=0}^{N\delta} \frac{(N\rho_{2})^{i}}{i!} + \left( \frac{\rho_{2}}{\rho_{1}} \right)^{N\delta} \sum_{i=N\delta+1}^{NC} \frac{(N\rho_{1})^{i}}{i!} \right) \\ &= \frac{(N\delta - k)!}{(N\rho_{2})^{N\delta - k}} \left( \sum_{j=0}^{N\delta} \frac{(N\rho_{2})^{N\delta - j}}{(N\delta - j)!} + \left( \frac{\rho_{2}}{\rho_{1}} \right)^{N\delta} \sum_{i=N\delta+1}^{NC} \frac{(N\rho_{1})^{i}}{i!} \right) \\ &= \sum_{j=0}^{N\delta} \frac{(N\rho_{2})^{k} (N\delta - k)!}{(N\rho_{2})^{j} (N\delta - j)!} + \sum_{j=1}^{N(C-\delta)} \frac{(N\rho_{1})^{j} (N\rho_{2})^{k} (N\delta - k)!}{(N\delta + j)!} \\ &= \rho_{2}^{k} \sum_{j=0}^{N\delta} \rho_{2}^{-j} \frac{N^{k} (N\delta - k)!}{N^{j} (N\delta - j)!} + \sum_{j=1}^{N(C-\delta)} \frac{(N\rho_{1})^{j} (N\rho_{2})^{k} (N\delta - k)!}{(N\delta + j)!}. \end{split}$$

ACM Trans. Model. Perform. Eval. Comput. Syst., Vol. 1, No. 1, Article 1. Publication date: January 2019.

Using Stirling's formula we obtain:

$$\lim_{N \to \infty} \frac{N^k (N\delta - k)!}{N^j (N\delta - j)!} = \frac{\delta^j}{\delta^k}$$

and then for the first term, using dominated convergence we have:

$$\lim_{N \to \infty} \rho_2^k \sum_{j=0}^{N\delta} \rho_2^{-j} \frac{N^k (N\delta - k)!}{N^j (N\delta - j)!} = \left(\frac{\rho_2}{\delta}\right)^k \frac{1}{1 - \frac{\delta}{\rho_2}}$$

For the second term we have using Stirling's formula that:

$$\lim_{N \to \infty} \frac{(N\rho_1)^j (N\rho_2)^k (N\delta - k)!}{(N\delta + j)!} = \left(\frac{\rho_1}{\delta}\right)^j \left(\frac{\rho_2}{\delta}\right)^k,$$

then, with dominated convergence:

$$\lim_{N \to \infty} \sum_{j=1}^{N(C-\delta)} \frac{(N\rho_1)^j (N\rho_2)^k (N\delta-k)!}{(N\delta+j)!} = \frac{\rho_1}{\delta - \rho_1} \left(\frac{\rho_2}{\delta}\right)^k$$

and, for  $0 \le k < N\delta$ , we obtain:

$$\lim_{N \to \infty} \widetilde{\pi}^N (N\delta - k) = \rho \left(\frac{\delta}{\rho_2}\right)^k$$

If  $\widetilde{Z}^N = \widetilde{X}^N - N\delta$  we have that the stationary distribution  $\widetilde{\mu}^N$  of  $\widetilde{Z}^N$  verifies, for j < 0, that:

$$\lim_{N \to \infty} \widetilde{\mu}^N(j) = \lim_{N \to \infty} \widetilde{\pi}^N(N\delta - (-j)) = \rho \left(\frac{\rho_2}{\delta}\right)^j$$

In the same way we compute, for  $0 \le k \le NC - N\delta$ ,  $\tilde{\pi}^N(N\delta + k)$ .

In Figure 8 we show the limit distribution and the stationary distribution for different values of N. We see that the limit distribution represents a good estimation of the stationary one for all N values.

3.3.2 Practical QoS criterion for  $\delta$  selection. Using Theorem 3.7 we can improve the average utilization of the spectrum while ensuring a small probability of interruption to the secondary users. Please note that the result is valid for  $\mu_1 = \mu_2$ . For the general case, we cannot obtain an analytical expression of the distribution but we can estimate  $\delta$  considering an equivalent system. If  $\mu_1$  and  $\mu_2$  are of the same order we can assume  $\mu = \min\{\mu_1, \mu_2\}$  (the worst case). Another approach considers a  $\mu$ -scaled system ( $\mu = \mu_1$ ,  $\lambda_1 = \lambda_1$  and  $\lambda_2 = \lambda_2 \mu/\mu_2$ ) [35]. Then, with the equivalent system, in the same way as in the Gaussian approximation, our proposal consists in relating the value of  $\delta$  with the probability that the process lives on  $\gamma$ , then 

$$P(\widetilde{X}_1^N + \widetilde{X}_2^N = CN) = P(\widetilde{X}^N = CN) = P(\widetilde{X}^N - N\delta = CN - N\delta).$$

According to Theorem 3.7 we can assume that:

$$P(\widetilde{X}_1^N + \widetilde{X}_2^N = CN) \approx \rho \left(\frac{\rho_1}{\delta}\right)^{N(C-\delta)}$$
(8)

for large values of N.

Assuming a threshold on the probability of interruption which can be represented by  $P(\widetilde{X}_1^N + \widetilde{X}_2^N = CN) \le \epsilon$  for certain  $\epsilon$  and considering NC as the total number of subchannels in the system, using equation (8) it is possible to obtain an upper bound of  $\hat{\delta} = \delta(N, C, \epsilon)$ .

Fig. 8. Limit ( $N \rightarrow \infty$ ) of stationary distribution and stationary distributions for different N values. Parameters: C = 5,  $\delta = 3$ ,  $\rho_1 = 1$ ,  $\rho_2 = 3.5$ .

As an example we made different sets of simulations changing the value of *N* considering the parameters  $\lambda_1 = 2$ ,  $\lambda_2 = 4$ ,  $\mu_1 = 4$  and  $\mu_2 = 5$ . Figure 9 shows the probability that the system is full for different values of *N*. In this case we have used  $\mu = 4$  (the most critical case). Considering  $\epsilon = 0.1$  we can conclude that if we need  $P(\widetilde{X}_1^N + \widetilde{X}_2^N = CN) \le 0.1$ , we obtain an upper bound of  $\delta$  ( $\hat{\delta}$ ) depending on *N* (see Table 4).

Table 4.	Upper bounds	to $\delta$ in order	to ensure	$P(\widetilde{X}_1^N$	$+ \widetilde{X}_2^N$	= CN)	≤ 0.1.

3.3.3 Simulations for the general case with different service rates. The asymptotic distribution obtained in Theorem 3.7 has the drawback that assumes equal services rates for PUs and SUs. This

ACM Trans. Model. Perform. Eval. Comput. Syst., Vol. 1, No. 1, Article 1. Publication date: January 2019.

Fig. 9. Interruption probability vs  $\delta$ . Parameters: C = 1,  $\lambda_1 = 2$ ,  $\lambda_2 = 4$ ,  $\mu_1 = 4$  and  $\mu_2 = 5$ .

hypothesis is needed because of the technique that we used to prove Theorem 3.7. Our proof, based
on [33], relies on the explicit computation of the stationary distribution for the original system and
for the scaled one, and in the calculus of the limit when the scaling factor *N* goes to infinity. This
approach is not suitable for different service rates as there is not a closed formula for the stationary
distribution. Then, a different approach would be necessary to obtain a non-Gaussian asymptotic
distribution in the general case.

Despite of this restriction, in 3.3.2 we have applied our results about geometric distribution to the case of different services rates in order to design an admission control policy. In addition, for different service rates, when the fixed point is in the admission control border, the asymptotic distribution is non-Gaussian.

Here we analyze with simulations the case with different service rates. We consider a deterministic 1110 admission control where the fixed point  $(x_1^*, x_2^*)$  of the PWSDS is at the admission control border 1111  $\gamma'$ . In this case we cannot obtain a Gaussian distribution as it is obtained when the fixed point is in 1112 the interior the region  $\{(x_1, x_2) : x_1 + x_2 < \delta\}$ . In this last case it actually does not matter if there is 1113 a deterministic admission control at  $x_1 + x_2 = \delta$  or we consider the free admission control policy. 1114 In both cases, if the fixed point is in the interior the behavior is similar. On the other hand, when 1115 the fixed point lies in  $\gamma'$ , fluctuations around the fixed point are asymmetric and much smaller than 1116 in the case of the interior fixed point, so that scaled by  $\sqrt{N}$  as in the Gaussian case we would not 1117 obtain such limit. 1118

We simulate two cases, with different parameters and the same deterministic admission control, 1119 one with the fixed point in the interior an the other at  $\gamma'$ . In both cases the starting point is the 1120 fixed point. For both cases we show the trajectories in Figure 10. The case at the right is more 1121 asymmetrical and shows less dispersion around the fixed point than the left one. In Figure 11 we 1122 show the kernel density estimations of the normalized fluctuations of  $X_1^N + X_2^N$  around the mean 1123 system utilization  $x_1^* + x_2^*$  and in Figure 12 the corresponding QQ-plots. In both figures it is more 1124 visible the asymmetry but specially that the distribution at the right is concentrated around zero, 1125 and cannot be approximated by a Gaussian. 1126

Right: N = 100, C = 1,  $\delta = 0.8$ ,  $\lambda_1 = 2$ ,  $\lambda_2 = 4$ ,  $\mu_1 = 4$  and  $\mu_2 = 5$ , kernel density estimation for the normalized variable  $X_1^N + X_2^N - 0.8$ .

3.4 Probabilistic admission control policy

Let us consider another class of admission control: a probabilistic admission mechanism where secondary users can access the system with a probability related to the number of users in the system. Let  $a(x_1, x_2)$  be the probability that a secondary user that arrives enters the system when there are  $x_1$  primary users and  $x_2$  secondary users. Then, when computing the entry rates for the whole system, the arrival rates of secondary users appear multiplied by this probability. Let us assume that  $a(x_1, x_2)$  is a Lipschitz function that vanishes close to the border  $\{(x_1, x_2) : x_1 + x_2 = C\}$ (as an example we could choose  $a(x_1, x_2) = 1 - (x_1 + x_2)/C$ ), that is:

$$\lim_{1+x_2 \to C} a(x_1, x_2) = 0$$

In this case we also have discontinuous transition rates in the border of the state space. Following the same lines as for the free admission case in Subsection 3.2 Proposition 3.3 we have:

 x

1:24

Fig. 12. Left:  $N = 100, C = 1, \delta = 0.8, \lambda_1 = 2, \lambda_2 = 1, \mu_1 = 5$  and  $\mu_2 = 4$ . Right:  $N = 100, C = 1, \delta = 0.8, \lambda_1 = 2, \lambda_2 = 4, \mu_1 = 4$  and  $\mu_2 = 5$ .

PROPOSITION 3.8. Let  $Q_1(x_1, x_2)$  and  $Q_2(x_1, x_2)$  be vector fields, both smooth in  $R_1 = \{(x_1, x_2) : x_1 + x_2 - C < 0\}$  and  $\gamma$  respectively such that

$$Q_1(x_1, x_2) = \begin{pmatrix} \lambda_1 - \mu_1 x_1 \\ \lambda_2 a(x_1, x_2) - \mu_2 x_2 \end{pmatrix}, \qquad Q_2(x_1, x_2) = \begin{pmatrix} \lambda_1 - \mu_1 x_1 \\ -\lambda_1 - \mu_2 x_2 \end{pmatrix}$$

and let  $n(x_1, x_2)$  be the normal vector to the boundary  $\gamma$  ( $n^T(x_1, x_2) = (1, 1)$  for all  $(x_1, x_2) \in \gamma$ ) then we have a PWSDS driven by the following equations.

If  $x_1 + x_2 < C$  or  $\lambda_1 \leq \mu_1 x_1 + \mu_2 x_2$ :

$$\begin{cases} x'_1 = \lambda_1 - \mu_1 x_1, \\ x'_2 = \lambda_2 a(x_1, x_2) - \mu_2 x_2. \end{cases}$$

If  $x_1 + x_2 = C$  and  $\lambda_1 > \mu_1 x_1 + \mu_2 x_2$ :

$$\begin{cases} x_1' = \lambda_1 - \mu_1 x_1, \\ x_2' = -\lambda_1 + \mu_1 x_1. \end{cases}$$

This system has a unique solution with initial condition  $(x_1(0), x_2(0))$ . Let:

$$(x_1(t), x_2(t))$$
 (9)

be the piecewise smooth dynamical system that is the solution to the previous equations with initial condition ( $x_1(0), x_2(0)$ ). Theorem 3.4 holds in this context.

This probabilistic admission control is different from the deterministic one. The solution presents sliding motion when  $\lambda_1/\mu_1 \ge C$  or when  $\lambda_1/\mu_2 \ge C$ . In the first case the system in stationary regime is always saturated by PUs, despite of the admission control. In the second case sliding motion depends on the initial condition but it does not influence the stationary regime.

Let us consider the fixed point  $(x_1^*, x_2^*)$  for the processes defined by (9). For  $\theta_1 = \lambda_1/\mu_1 < C$  and  $\theta_2 = \lambda_2/\mu_2$ , we have  $x_1^* = \theta_1$  and  $x_2^*$  verifies the equation  $x_2^* = \theta_2 a(\theta_1, x_2^*)$ . Therefore,  $x_2^*$  is unique if we assume that the equation  $\theta_2 a(\theta_1, x) - x = 0$  has an unique solution. In the example, with  $a(x_1, x_2) = 1 - x_1 + x_2/C$ ,  $x_2^*$  can be obtained explicitly.

PROPOSITION 3.9. Considering  $a(x_1, x_2)$  continuous with  $\lim_{x_1+x_2 \to C} a(x_1, x_2) = 0$  and defining  $(x_1^*, x_2^*)$ as the PWSDS fixed point, then:

- a. If θ<sub>1</sub> < C, then x<sub>1</sub><sup>\*</sup> = λ<sub>1</sub>/μ<sub>1</sub> and x<sub>2</sub><sup>\*</sup> = θ<sub>2</sub>a(θ<sub>1</sub>, x<sub>2</sub><sup>\*</sup>) where (x<sub>1</sub><sup>\*</sup>, x<sub>2</sub><sup>\*</sup>) ∈ R<sub>1</sub> and the mean system utilization will be θ<sub>1</sub> + θ<sub>2</sub>a(θ<sub>1</sub>, x<sub>2</sub><sup>\*</sup>).
  b. If θ<sub>1</sub> ≥ C, then (x<sub>1</sub><sup>\*</sup>, x<sub>2</sub><sup>\*</sup>) = (C, 0) and the mean system utilization will be C.

SKETCH OF THE PROOF. Results follows from similar arguments than in Proposition 3.5. In addition we could assume hypotheses about the probabilistic admission control function  $a(x_1, x_2)$  that ensures asymptotic stability of the solutions (for example negative real part of eigenvalues for the linearized system). This condition follows in the example  $a(x_1, x_2) = 1 - x_1 + x_2/C$ , where we have a linear ODE. (See Figure 13 in order to analyze the vector field behavior in two different cases.) 

Fig. 13. Vector field for Case 1 (left):  $N = 100, C = 1, \lambda_1 = 2, \lambda_2 = 1, \mu_1 = 5, \mu_2 = 4$  and Case 2 (right):  $N = 100, C = 1, \lambda_1 = 2, \lambda_2 = 4, \mu_1 = 4, \mu_2 = 5$ . The continuous line represents y.

REMARK. For case a. of Proposition 3.9, for initial conditions where there is not sliding motion, it is possible to apply the same results about Gaussian limits. Let  $(x_1, x_2)$  be the trajectory of the solution with initial condition  $(x_1(0), x_2(0))$ . If:

$$\lim_{N \to +\infty} \sqrt{N} [(X_1^N(0), X_2^N(0)) - (x_1(0), x_2(0))] = \chi(0)$$

with  $\chi(0)$  deterministic, then  $\sqrt{N}[(X_1^N, X_2^N) - (x_1, x_2)] \Rightarrow \chi$ , where  $(\chi(t))$  is a Gaussian process whose *matrix can be determined explicitly by:* 

$$Cov(\chi(t),\chi(r)) = \int_0^{t\wedge r} e^{A(t-s)} G(x_1(s),x_2(s)) e^{A(r-s)} ds$$

where

$$A = \begin{pmatrix} -\mu_1 & 0\\ 0 & -\mu_2 \end{pmatrix},$$
$$G(x_1(s), x_2(s)) = \begin{pmatrix} \lambda_1 + \mu_1 x_1(s) & 0\\ 0 & \lambda_2 a(x_1(s), x_2(s)) + \mu_2 x_2(s) \end{pmatrix}$$

In particular in Figure 14 we show the simulation of one trajectory of the scaled Markov process and the trajectory of the ODE. In the same way as in Section 3.2, considering a large finite value of *N* we can calculate the covariance matrix  $\Sigma(\infty)$  solving Equation (7). For instance in Figure 15 we illustrate different confidence ellipses (for different N values) for the case of Figure 14.

The main contributions of this work are the analysis and characterization of a possible model of 1317 spectrum sharing in cognitive radio networks that improve the average utilization of the spectrum 1318 1319 while ensuring a small probability of interruption to the secondary users.

We considered a continuous time Markov chain that represents the population of the different 1320 1321 types of users in the system. We formulated the associated fluid model and we studied its solutions. We studied the behavior of the system considering deterministic and probabilistic admission control 1322 1323

mechanisms by means of the study of fixed points and the related asymptotic distributions. For
the deterministic case we obtained non-Gaussian and Gaussian asymptotic distributions being
the non-Gaussian result one of the main contributions of the paper. It is an input for future work
our preliminary results about asymptotic distribution in the non-Gaussian case. We aim to find
theoretical results in the general case with different service rates.

For systems with a large number of users we presented practical design criteria to guarantee
with high probability that secondary users in the system will not have service interruptions. These
design criteria were suggested by a theoretical analysis and supported by simulations.
